Abstract: The aim of the paper is to explore the association between environmental performance and income level in the world economy in 2016. Data from Yale University and World Bank are used in a cross-country regression analysis comprising 166 countries. The gross Domestic Product per capita (based in purchased power parity, constant 2011 international dollars) in these countries is positively associated with the environmental performance index (EPI) calculated by Yale and Columbia University in 2016. Furthermore, the causality of this relationship is from GDP per capita to Environmental Performance and both Environmental Health (EH) and Ecosystem Vitality (EV) are positively associated with GDP per capita. Environmental Health (EH) is stronger related to GDP per capita, meaning that investments in public health, sanitation and infrastructure are increasing as countries develop.

Keywords: sustainable development, environmental economics, economic growth, cross-sectional models

JEL Codes: Q01, Q50, O40, C21

Introduction

The growing concern about sustainable development induced in recent years the term of "environmental performance" universally adopted by environmental experts, economists, environmental policy analysts as well as by decision makers. Human activity and economic growth impact on living and non-living systems, including ecosystems, land, air and water. As a reverse, environmental quality (air, water, plants, animals, biodiversity, climate, soils quality) affects our biological lives as well as the efficiency and effectiveness in producing goods and services. Worldwide environmental degradation makes people, experts and policy makers worried about the issue of the link between economic growth and environmental degradation or performance, since it is generally believed that a high level of environmental performance is associated with a high environmental quality of life and life standard.

Neagu O., Ardelean D.I., Lazăr V. (2017)

How is environmental performance associated with economic growth? A world cross-country analysis

It is difficult to measure the impact of income or economic growth on environmental performance due to the fact that it has several aspects (water, air, soil, biodiversity, etc.) which must be included and combined in one single construction. Furthermore, in order to be relevant for environmental analysts and for environmental policy makers, any composite index of a country's environmental performance should capture national efforts to protect the natural environment.

The Environmental Performance Index (EPI) calculated by Yale University in cooperation with Columbia University focuses on measurable outcomes that can be linked to environmental policy targets, encompassing 22 environmental indicators.

Noting that there are very few studies focused on exploring the environment-income relationship based on this index, the intention of the present authors' paper is to highlight the link between the environmental performance expressed through EPI and the income level in the world economy in 2016.

The paper is organised as follows: after the introduction, the section of literature review exposes the main relevant studies for the paper's topic. The methodology and data are described in the third section, the fourth section is dedicated to main findings and the last one contains the paper's conclusions.

1. Literature review

The issue of income-environment relationship has been the focus of a huge amount of empirical studies in last 25 years.

Shafik and Bandyopadhyay (1992) explored the relationship between economic growth and environmental quality in 66 countries by analyzing patterns of environmental transformation at different income levels. They looked at eight indicators of environmental quality (deforestation, dissolved oxygen, sulfur dioxide, access to safe water and urban sanitation, carbon emissions, municipal waste, suspended particulate matter, fecal coliform) in response to economic growth in a large number of countries and across time. Income has a significant effect on all environmental quality indicators, but the relation between income and environment is not simple: as incomes rise most indicators decrease initially, except access to safe water and urban sanitation - problems that higher incomes will solve. Countries with high rates of investments and economic growth put pressure on natural resources, particularly in term of pollution, but some indicators, as deforestation and sulfur dioxide tend to improve with higher incomes.

Grossman and Krueger (1995) examined also the relationship between income per capita and various environmental indicators (urban air pollution, oxygen regime in rivers basins, fecal contaminations, and contamination by heavy metals) in 42 countries. They found no evidence that environmental quality deteriorates steadily

with economic growth and for most environmental indicators economic growth brings an initial phase of deterioration followed by a phase of improvement.

Other authors, such as Islam (1997) demonstrated that there is no rule that environment has to first deteriorate with economic growth and improve later, by estimating the income - environment relationship for Asia and comparing it with the same of other regions of the world. He suggested also that the role of income to explain pollution dynamics is limited.

For a better understanding of the income-environment relationship, its determinants were explored (Panayotou, 1997) and it was decomposed into its structural sources: level effect, composition effect and abatement effect, by using global data. The level and composition effects were found to follow a linear and quadratic evolution and the abatement effect is found to be downward sloping and of backward-J shape (Islam et al., 1998).

This inverted U-shaped pattern identified in several studies as displaying the relationship between income and environmental indicators has given rise to the Environmental Kuznets's Curve Hypothesis. This hypothesis emerged from the initially theory of Kuznets (1955) stating that the income-inequality relationship should follow an inverse U-shaped along the development process, first rising with industrialisation and then declining, as the labour productivity increases. According to this hypothesis of Kuznets, environmental quality deteriorates in initial phase of growth and then improves at high levels of income.

A vast empirical literature dedicated to Environmental Kuznets's Curve captures the scale, composition, income and technique effects using simple or multiple variables models and various econometric techniques where environmental variables (i.e. pollution, water quality, energy use, biodiversity loss, municipal waste, ecological footprint, deforestation, etc.) are dependent variables and independent variables are income, income squared or income cube (Holtz-Eakin and Selden, 1992; Selden and Song, 1994; Selden and Song, 1994, 1995; Shafiq, 1994; Grossman and Krueger, 1995; Cole et al., 1997; Moomaw and Unruh, 1997; Stern, 1998; de Bruyn et al., 1998; Munasinghe, 1999; Stern and Common, 2001; Harbaugh et al., 2002; Bimonte, 2002; Perman and Stern, 2003; Lee and List, 2004; Dinda, 2004 and 2005; Pertinelli and Strobl, 2005; Shen, 2006; Saboori et al., 2011; Shahbaz et al., 2012; Taguchi, 2012; Tiwari et al. 2013).

There are also a group of studies where no validity of EKC was found (i.e. Seppälä et al. 2001; Stern, 2004; Caviglia-Harris et al. 2009), as well as studies concluding that the Kuznets curves can be true for a cross-section of countries at a specific point in time (Booth, 2017) or founding an inverse global environmental Kuznets curve (Jha and Murthy, 2003). Other studies are concerned on globalization effects

Neagu O., Ardelean D.I., Lazăr V. (2017)

How is environmental performance associated with economic growth? A world cross-country analysis

on environmental Kuznets Curve (i.e. Tisdell, 2001) or found a reverse Kuznets Curve (i.e. Bulte and van Soest, 2001).

The main problem of all these studies was to measure the environment degradation and several statistical indicators were proposed and used: depletion and degradation of forest, water, land resources, air pollution, greenhouse gases pollution, etc. Several attempts were made to construct composite indexes to express the environmental quality or depreciation, such as: Environmental Quality Index (EQI), Environmental Indicators developed by OECD and Environmental Performance Index (EPI).

EQI was developed for all counties in the United States. It uses indicators from the chemical, natural, built, and social environment, based on data collected and monitored by US Environmental Protection Agency (EPA).

OECD (2003) developed a set of environmental indicators regarding: climate change, ozone layer depletion, eutrophication, acidification, toxic contamination, urban environmental quality, biodiversity, cultural landscapes, waste, water resources, forest resources, fish resources, soil degradation, material resources and other socio-economic indicators. A part of them are used jointly with the Statistical Office of the European Commission (Eurostat).

The UNDP's experts include in the concept of Environment Sustainability the following statistical indicators: Renewable energy consumption (% of total final energy consumption), Carbon dioxide emissions (tones per capita), Forest area (% of total land), Fresh water withdrawals (% of renewable water resources) (UNDP, 2016).

The EPI builds on measures relevant to two core objectives: (a) reducing environmental stress to human health (the environmental health) and (b) protecting ecosystems and natural resources (the ecosystem vitality). The present paper used this index to explore the income-environment relationship; therefore this index is exposed in the second section, Data and Methodology.

2. Data and methodology

The paper uses regression analysis techniques in order to put in evidence the association between environmental performance and income level in the world economy in 2016. Specifically, a cross-country regression is developed, taking into consideration the environmental performance as dependent variable and the level of economic development as independent variable.

For the use of this paper, the environmental performance is expressed by the metrics calculated by the Yale Data-Driven Environmental Group at Yale University and Center for International Earth Science Information Network at Columbia University in collaboration with the Samuel Family Foundation, McCall

Neagu O., Ardelean D.I., Lazăr V. (2017)

How is environmental performance associated with economic growth? A world cross-country analysis

MacBain Foundation, and the World Economic Forum, namely the Environmental Performance Index (EPI). It ranks countries' performance in two areas: protection of human health and protection of ecosystems. It scores national performance in nine issue areas comprised of 22 indicators measuring the country proximity to meet the internationally established targets and to compare their environmental performance. EPI has two components: Environmental Health (EH) and Ecosystem Vitality (EV). The first component comprises of health impacts expressed by environmental risk exposure (risk of water and air pollution to human health) air quality (population exposure to PM 2.5 and health risk from PM 2.5 exposure, population whose exposure is above WHO thresholds, population exposure to NO₂) and water and sanitation (exposure to unsafe sanitation and population lacking access to sanitation, exposure to insafe water quality and population lacking access to drinking water). The second component includes: water resources (wastewater treatment), agriculture (nitrogen use efficiency and nitrogen balance), forests (change in forest cover), fisheries (fishing stock overexploited and collapsed) biodiversity and habitat (protected terrestrial biome area, marine protected areas, species under protection), climate and energy (performance in change in CO₂ emissions per unit GDP, change in CO₂ emissions from electricity and heat production). The level of aggregation is 50% for each component (Hsu et al., 2016).

The economic development is expressed by GDP per capita based on purchase power parity (PPP) constant 2011 constant international dollars extracted from World Bank Database, for 166 countries corresponding to those the Environmental Performance Index is calculated by Yale and Columbia University. The values of EPI, EH, EV and GDPper capita for the 166 economies are exposed in Annex 1.

We analyse the stochastic dependence between environmental performance and economic development through a regression equation:

$$y = f(x) + \varepsilon \quad (1)$$

where y is expressed by EPI, x is measured by GDP per capita and ε is the significance error.

We presume that there is linear dependence between the two variables and we intend to check this assumption. In a graphical representation (Figure 1) we notice that the behaviour of the function y is quadratic, not linear, it never reach a maximum or minimum y value and that the impact of independent variable (x) on dependent variable (y) decreases as the value of y increases.

Neagu O., Ardelean D.I., Lazăr V. (2017)

How is environmental performance associated with economic growth? A world cross-country analysis

Figure 1 GDP per capita (PPP) versus EPI in the world economy, 2016

Source: authors' own computation based on World Bank and Yale and Columbia University data

Taking into consideration the above conclusions, we choose a linear-log model, as follows:

$$EPI_i = \alpha + \beta \cdot \log GDPpc_i + \varepsilon \quad (2)$$

where EPI_i means Environmental Performance Index for the country i , $GDPpc_i$ is the Gross Domestic Product per capita for country i , α is a constant, β is the regression coefficient and ε is the significance error.

In order to explore in detail the impact of economic growth we use the equation 2 for the two components of Environmental Performance Index:

Environmental Health (EH):

$$EH_i = \alpha_h + \beta_h \cdot \log GDPpc_i + \varepsilon_h \quad (3)$$

Ecosystem Vitality (EV):

$$EV_i = \alpha_v + \beta_v \cdot \log GDPpc_i + \varepsilon_v \quad (4)$$

We estimated the regression parameters of equations (2)-(4) by using the OLS method within the EViews 9.0 software.

3. Main findings

The estimated equation 2 is the following:

$$EPI = -25.48974 + 23.4682 \cdot \log GDP_{pc} \quad (5)$$

(0.0000) (0.0000)

We can follow the dependence of EPI to GDPpc in the Figure 2:

Figure 2 EPI versus logGDP per capita in the world economy, 2016

Source: authors' own computation based on World Bank and Yale and Columbia University data

We notice that, mainly, all examined countries are grouped around the red regression line (Figure 2), but according to the Annex 2, the first 10 countries ranked by GDP per capita are not the first when the ranking criterion is EPI. Finland, Iceland and Sweden are on the first positions according to the values of EPI, but according to GDP level, they are positioned on Finland on the 10-th, Iceland on the 14-th and Sweden on the 12-th places. Qatar, Brunei, United Arab Emirates, the most rich countries in the world have modest environmental performances.

The statistical cross-country model (Table 1) can be validated due to the fact that the value of Prob (F-statistic) is 0.000 lower than 0.05, the significance threshold. The value of Prob. for the constant C and the coefficient of logGDPpc is 0.000 (<0.05).

Sum squared resid	10306.61	Schwarz criterion		7.028020
Log likelihood	-578.2137	Hannan-Quinn criter.		7.005745
F-statistic	394.8674	Durbin-Watson stat		1.958068
Prob(F-statistic)	0.000000			

Source: authors' computation by using EViews 9.0 software

The determination coefficient (R-squared) is 0.706549 meaning that 70.65% of the variation of EPI can be explained by the variation of logGDP per capita. The value of adjusted R-squared (0.704760) is close to the R-squared meaning that our sample is relevant for an accurate representation of the reality.

The parameter β has the value of 23.46822 showing that for an increase of percentage point of GDP per capita, EPI will increase with 23.46822 units, if other factors are remaining constant.

In order to test the heteroskedasticity of errors, we used the White test (Table 2).

Table 2-Heteroskedasticity test for equation 2

Heteroskedasticity Test: White

F-statistic	1.212489	Prob. F(2,163)	0.3001
Obs*R-squared	2.433408	Prob. Chi-Square(2)	0.2962

Neagu O., Ardelean D.I., Lazăr V. (2017)

How is environmental performance associated with economic growth? A world cross-country analysis

The value of Obs*R-squared (1.2124289) < $\chi^2_{0,05;2} = 5.99$ meaning that the null hypothesis is accepted and the errors are homoskedastic, for a significance level of 5%: the variation of dependent variable being constant for any level of independent variables.

We intend to check the autocorrelation of errors by using the Breusch-Godfrey Serial Correlation LM Test (Table 3). The value of Obs*R-squared (1.294041) < $\chi^2_{0,05;2} = 5.99$, meaning that the null hypothesis is accepted and the errors are independent (not autocorrelated).

Table 3- Errors autocorrelation detection

Breusch-Godfrey Serial Correlation LM Test:

F-statistic	0.636390	Prob. F(2,162)	0.5305
Obs*R-squared	1.294041	Prob. Chi-Square(2)	0.5236

Source: authors' computation by using EViews 9.0 software

In order to check the causality sense of the relationship between logGDP per capita and environmental performance index (EPI), we used the Granger causality test from Eviews 9.0. The result displayed in the Table 4 show us that the value of F-statistic (36.4485) is higher than $F_{0,05;1,\infty} = 3.84$, meaning that the null hypothesis is rejected and logGDP per capita does cause EPI.

Table 4-Causality test

Pairwise Granger Causality Tests

EPI does not Granger Cause LOGGDPPC		0.68069	0.5077

Source: authors' computation by using EViews 9.0 software

Both Environmental Health (EH) and Ecosystem Vitality (EV) are positively associated with GDP per capita (Figure 3a) -b) and Table 5). The link is stronger for Environmental Health, R-squared is 0.684909 compared to 0.380693 for

Neagu O., Ardelean D.I., Lazăr V. (2017)

How is environmental performance associated with economic growth? A world cross-country analysis

Ecosystem Vitality. The dispersion of Ecosystem Vitality in the group of examined countries is higher than the Environmental Health (Figure 3a and Figure 3b), reflecting that, in terms of natural resources management and biodiversity protection, the world economy should be more effective and more concern should be given by national authorities to preserve and maintain the vitality of natural heritage as the economic activities evolves.

Figure 3a) Environmental Health and logGDP per capita

Figure 3b) Ecosystem vitality and logGDP per capita

Source: authors' own computation based on World Bank and Yale and Columbia University data

For both variables (EH and EV), the cross-country regression model can be validated (Table 5), due to the fact that the value of Prob(F-statistic) is 0.000(<0.05).

In the case of Environmental Health (EH), a percentage change of GDP per capita can lead to an increase of 28.50553 units of EH. The influence of GDP per capita on the change of Ecosystem Vitality (EV) is weaker, a change of one percentage point of GDP per capita is leading to an increase of EV with 18.43201 units.

4. Conclusions

The aim of the paper was to explore the association between environmental performance and the level of income in the world economy in 2016.

We found a positive strong association between economic growth expressed by log GDP per capita and the values of environmental performance index (EPI) in 2016, in the world economy (166 countries). The cross-country model is statistically validated and reflects the beneficial influence of GDP per capita on the environmental performance, suggesting that as wealth increases, national environmental performance improves.

Both Environmental Health (EH) and Ecosystem Vitality (EV) are positively associated with GDP per capita, but Environmental Health (EH) is stronger related to GDP per capita, meaning that investments in public health, sanitation and infrastructure are increasing as countries develop.

Ecosystem Vitality (EV) scores are more dispersed in their relationship with GDP per capita. For example, rich countries as Qatar, Kuwait, Oman and United Arab

Neagu O., Ardelean D.I., Lazăr V. (2017)

How is environmental performance associated with economic growth? A world cross-country analysis

Emirates underperform on their environmental protection to other wealth and developed countries.

The limits of the study consist on the fact that the analysis is made only for one year, 2016. A combined, across time and across country, analysis would highlight more details of the link between environmental performance and economic growth in the world and to show how if there is a difference on how the economic growth rate is associated to the environmental performance in developed and developing countries. Another direction to which the research could be extended is a cross-country comparison of costs to reach a certain environmental performance and rate depending to the GDP per capita, as Ardelean and David (2013) suggested in their paper.

Our findings are relevant for national governments from developed and developing countries alike when they design their public environmental policies meant to preserve and maintain the natural heritage and to improve the ecosystem and natural resources management.
